 - sign test
 - Wilcoxon signed rank test

bootstrap confidence intervals

Confidence interval for normal data

ny func. of data you use to estim. your poram.

A point estimate for an unknown parameter μ is some function of the data.

EXAMPLE For a sample $X_1, \ldots, X_n \sim N(\mu, \sigma^2)$, we can estimate μ using the estimating statistic \bar{X} . The point estimate for μ is thus $\hat{\mu} = \bar{X}$.

Recall that a confidence interval for an unknown parameter μ is a randominterval around the point estimate, containing μ with, e.g., 95% confidence.

EXAMPLE (continued) An (asymptotic) 95%-confidence interval for μ is the interval $[\bar{X} - m, \bar{X} + m]$, where $m = 1.96s/\sqrt{n}$.

rand. obj. dep. or

The margin $m=1.96s/\sqrt{n}$ is based on the asymptotic normality of \bar{X} and the fact that s is a good estimator of σ . If in the CI we use the upper t-quantile $t_{0.025}$ n_{-1} instead of $z_{0.025} \approx 1.96$, the CI will be bigger (i.e., more "conservative") because always $t_{\alpha,n-1}>z_{\alpha}$, but $t_{\alpha,n-1}\to z_{\alpha}$ as $n\to\infty$.

Eduard Belitser EDDA, Lecture 2 4 / 34

Confidence interval for nonnormal data

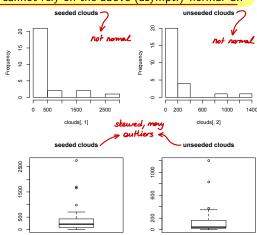

If we have a (small) sample from an unknown distribution and the distribution of \bar{X} is not close to normal, we cannot rely on the above (asympt.) normal CI.

EXAMPLE

Estimate the rainfall means of the two clouds data sets: seeded (with a chemical, silver nitrate, to cause a rainfall) and unseeded

- > c1=clouds[,1] # seeded
- > c2=clouds[,2] # unseeded
- > T1=mean(c1): T2=mean(c2) > T1
- Γ17 441.9846 ·
- T1 > T2 > T2 Γ1] 164.5619

How to determine confidence intervals?

- Bootstrap confidence interval # 1/2 we de dist. -> Smulate II to estim. dist. = bootstr
- of test

bootstrap CI 00000000

- Suppose we have a data sample $X = (X_1, \dots, X_n)$ and an estimating statistic $T = T(X_1, ..., X_n)$ for a parameter, say, θ .
- We use simulation to find the distribution of the estimating statistic T(X). The bootstrap CI is then found from this simulated distribution.
- The bootstrap method estimates the distribution of T by creating a sample of representative values T_1^*, \ldots, T_B^* with B large.
 - The basic bootstrap confidence interval of level $1-\alpha$ is

$$[2T-T^*_{(1-\alpha/2)},2T-T^*_{(\alpha/2)}],$$

 $\beta \longrightarrow always b.w.$

vestons of $T \rightarrow rejones$.

where $T_{(\beta)}^*$ is the T^* -value such that $\beta \times 100\%$ of the T^* -values are lower than $T_{(\beta)}^*$. $T_{(\beta)}^*$ is called the sample β -quantile of the sample T_1^*, \ldots, T_B^* . enough In R: the sample β -quantile of $T^* = (T_1^*, \dots, T_R^*)$ is $T_{(\beta)}^* = \text{quantile}(T^*, \beta)$.

- quantile: The there are
- The bootstrap estimate for the variance of statistics T(X) is given by $\widehat{\mathrm{Var}}(T) = S_{T^*}^2 = \frac{1}{B-1} \sum_{b=1}^{B} \left(T_b^* - \overline{T^*} \right)^2.$ In R: $S_{T^*}^2 = \mathrm{var}(T^*)$

mean, the

begin = small. This bootstrap CI is constructed in such a way that it uses T. A simplier version of **quant** and bootstrap CI (called percentile bootstrap CI): $T_{(\alpha/2)}^*, T_{(1-\alpha/2)}^*$ the one mend = bip. quent:

Heuristics for basic bootstrap CI

We interpret T_1^*, \ldots, T_B^* as realizations of some random variable T^* . Then $-lphapprox \mathrm{P}\Big(T_{(lpha/2)}^*\leq T^*\leq T_{(1-lpha/2)}^*\Big)$ (percentile bootstrap CI $[T_{(lpha/2)}^*,\,T_{(1-lpha/2)}^*]$) $= P\left(T_{(\alpha/2)}^* - T \le T^* - T \le T_{(1-\alpha/2)}^* - T\right) \leftarrow$ $pprox \mathrm{P}\Big(T^*_{(lpha/2)}-T\leq T- heta\leq T^*_{(1-lpha/2)}-T\Big)$ we think true T as heta as a pood estim. $= P\left(2T - T^*_{(1-\alpha/2)} \le \theta \le 2T - T^*_{(\alpha/2)}\right),$ which gives us the basic bootstrap confidence interval for θ : $[2T - T^*_{(1-\alpha/2)}, 2T - T^*_{(\alpha/2)}].$ \nearrow now T is involved !

Eduard Belitser EDDA, Lecture 2 7 / 34

How to generate T^* -values

The generation of T^* values is as follows.

Repeat B times (i = 1, ..., B):

- generate a surrogate data set X_1^*, \ldots, X_n^* by sampling n values from the original data set X_1, \ldots, X_n with replacement,
- compute $T_i^* = T(X_1^*, \dots, X_n^*)$ for the surrogate sample.

This procedure yields T_1^*, \ldots, T_B^* .

w/o repl. = you
get some dataset
w/repl. = you get
one val.s may times o

Notice that we sample from the data that we have. Some data points X_i may be chosen more than once amongst the X^* -values, whereas other data points X_i may not be chosen at all. We do not introduce any new X-values, we only determine new T^* -values. This bootstrap procedure is called **empirical bootstrap**. How many different resamples are possible from a sample of size n? The number of ways to place n objects into n bins (some bins may be empty, i-th bin contains the copies of X_i). The method of stars and bars yields $\binom{2n-1}{n-1} = \binom{2n-1}{n}$. If you want a reference and a rule of thumb for B, Wilcox (2010) writes "599 is recommended for general use."

Eduard Belitser EDDA, Lecture 2 8 / 34

Bootstrap CI in R: example with cloud sets

EXAMPLE (continued) Determine this interval for the seeded clouds (c1):

```
> B=1000
> Tstar=numeric(B)
> for(i in 1:B) {
                                                    generate X_1^*, \ldots, X_n^*
   Xstar=sample(c1,replace=TRUE)
                                                    compute T_b^*, b = 1, \dots B
  Tstar[i]=mean(Xstar) }
                                                    determine T^*_{(\alpha/2)}
> Tstar25=quantile(Tstar, 0.025)
> Tstar975=quantile(Tstar, 0.975)
                                                    determine T^*_{(1-\alpha/2)}
> sum(Tstar<Tstar25)
Γ17 25
> c(2*T1-Tstar975,2*T1-Tstar25)
176.8857 668.9462
```

The 95% bootstrap confidence interval for the population mean of seeded clouds is [177, 669] around its mean T1=442.

For unseeded clouds the interval is [42, 254] around its mean T2=165.

Eduard Belitser EDDA. Lecture 2 9 / 34 bootstrap CI 0000000

- The smaller the CI, the better. The obtained two CI's are very large, because the estimating statistic \bar{X} is not robust against outliers.
- A robust estimator for location is median(X), estimating the population median. For the clouds data, the median is smaller than the mean.
- The 95% bootstrap CI for the median of seeded clouds is [139, 326] ([177, 669] for the mean); unseeded clouds: [-20, 62] ([42, 254] for the mean).
- For both data sets: the CI for the median is shorter and contains lower values. This confirms that the median is more robust than the mean.

General discussion on bootstrap confidence intervals

- Repeating the computation of a bootstrap confidence interval will always take 0 yield a different interval. Enlarging B will reduce the variation. here
- The bootstrap interval still depends only on the sample X_1, \ldots, X_n .
- If the original data X_1, \ldots, X_n caries little information about the parameter θ , the bootstrap interval will be off as well.

Eduard Belitser EDDA. Lecture 2 bootstrap tests

ldea

in bootstr. test we have addit. source of info.

- Suppose we are given
 - a sample X_1, \ldots, X_n ,
 - a null hypothesis H_0 : some claim about the population distribution,
 - a (sensible) test statistic $T = T(X_1, \dots, X_n)$

but we lack

• the distribution of T under H_0

 Then we cannot perform the test, because we do not have a critical value for T, that acts as border between rejecting and not rejecting H_0 .

- But if we somehow can simulate "pseudo-observations" characterizing H_0 , we can use a bootstrap test.
- It uses simulations to "mimic" the distribution of T under H_0 .

For a bootstrap test, no standard R-command — we have to program it ourselves.

Eduard Belitser EDDA. Lecture 2 12 / 34

Set up of a bootstrap test

Given our sample X_1, \ldots, X_n , we can compute the test statistic $T = T(X_1, \ldots, X_n)$ based on our sample.

Simulating the distribution of T under H_0 in the bootstrap fashion means generate a bunch of surrogate T-values (T_1^*, \ldots, T_B^*) that are representative values for T under H_0 . hetter than X = shuffl. X

The simulation set up is

• repeat B times (i = 1, ..., B):

- _ if Ho is very specific = better sample.
- 1 generate a surrogate data sample X_1^*, \dots, X_n^* (of the same sample size as original data set) according to H_0 ,
- 2 Compute the test statistic $T_i^* = T(X_1^*, \dots, X_n^*)$ for the surrogate sample.
- compare the T-value of the original data to the surrogate T^* -values and determine a p-value. \longrightarrow less prob. $T^* = reject rep., more prob. <math>T^* = accept. rep.$

By simulating the unknown distribution we make an estimation error. This error can be made arbitrarily small by choosing B large enough.

Eduard Belitser EDDA, Lecture 2 13 / 34

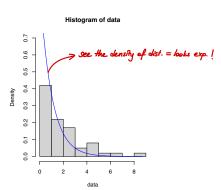

Bootstrap test: implementation in R(1)

We wish to test $H_0: X_i \stackrel{iid}{\sim} \mathsf{Exp}(1), i = 1 \dots, n$, i.e. the data are a random sample from the standard exponential distribution.

First plot a histogram of the data and the density Exp(1)corresponding to H_0 .

- > hist(data,prob=T,ylim=c(0,0.7))
- > x=seq(0,max(data),length=1000)
- lines(x,dexp(x),type="l",col="blue")

 H_0 seems plausible.

Eduard Belitser EDDA. Lecture 2 14 / 34

Bootstrap test: implementation in R(2)

As test statistic we use $T(X_1, ..., X_n) = \max(X_1, ..., X_n)$. The *p*-value is computed as the proportion of T^* -values exceeding the T-value.

a prob.

Bootstrap test: discussion

> T* comes from truth

- The resulting *p*-value depends on the realised *T**-values. It is recommended to repeat a bootstrap test a few times to see whether the *p*-value is stable.
 - When B is too small, there is a lot of variation in the p-value, in that case B should be increased. In most cases B = 1000 is adequate.
- A bootstrap test can be performed with any test statistic. E.g., in the example taking min as a test statistic yields a bootstrap *p*-value of about 0.19 (check this yourselves!) and does not lead to rejecting *H*₀.
- The difference between the simulation of T^* -values for bootstrap confidence intervals and bootstrap tests is in the way the X_1^*, \ldots, X_n^* are generated. For confidence intervals you draw X_i^* 's from the original sample, whereas for tests you generate X_i^* 's according to H_0 .

bootstr. test = better and more precise than b.s. C.l. but Hb must be v. specific

Eduard Belitser EDDA, Lecture 2 16 / 34

one sample (or two paired samples) from a normal distribution

t-test for one sample

Setting:

the data (X_1, \ldots, X_n) is a result of an experiment with one <u>numerical outcome</u> per experimental unit. Interest is in the location of the population distribution.

Design:

→ e.g. mean, median

- Take a random sample of experimental units from the relevant population
- Measure the outcome on each unit

EXAMPLE Measurement of the height of 4 years old children.

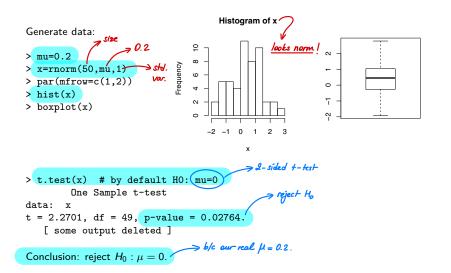

EXAMPLE Measurement of the yearly amount of sun hours in diff. countries.

Analysis:

- t-test assumes that the data $(X_1, ..., X_n)$ stems from a <u>normal</u> distribution (or, at least, approximately normal).
- Test about the population mean μ : $H_0: \mu \left\{\begin{array}{c} = \\ \leq \\ \end{array}\right\} \mu_0$ vs. $H_1: \mu \left\{\begin{array}{c} \neq \\ \geq \\ \end{array}\right\} \mu_0$.
- The test statistic $T = \sqrt{n(X \mu_0)/s}$ has the t_{n-1} -distribution under H_0 .

Eduard Belitser EDDA, Lecture 2 18 / 34

One sample t-test in R

> qqnorm(x)

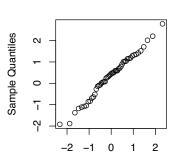

One sample t-test in R: diagnostics

- t-test is based on the (appr.) normality assumption, need to check this.
- The assumption of normality is crucial. If the data do not follow a normal distribution, the p-value from the t-test cannot be trusted.

Normal Q-Q Plot

Besides qqnorm, one can also look at hist, shapiro.test and boxplot.

The main normality checks in this course are histogram and qqnorm. Sometimes, the Shapiro-Wilk normality test shapiro.test is also to be be reported (especially when it rejects normality). *

Theoretical Quantiles

Eduard Belitser EDDA, Lecture 2 20 / 34

Setting and design for two paired samples

Setting:

, comes in pairs

An experiment with two numerical outcomes per experimental unit. Interest is in a possible difference between the two outcomes.

EXAMPLE Comparing pain relief by a dedicated drug or by a placebo. Both treatments are applied to every individual (with recovery time in between).

EXAMPLE Comparing two car tire brands by putting both brands of tire on the same car and measuring the tires' wear.

Design:

- Take a random sample of experimental units from the relevant population.
- Measure the two outcomes on each unit (which are clearly related).
- The experiment should be set up so that any other type of "dependence" is eliminated and a difference in outcomes is due to the "treatment" only.

Remark. If subjects must perform two tasks, then they should be allowed sufficient time between the tasks to recover and forget. If a learning effect (the first measurement influences the second) is suspected, then, if possible, randomize the order of the two treatments within the units. The analysis must then follow the cross over design (studied later), not the paired samples design as discussed here.

Paired t-test: analysis

• Data $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)$

now back to 1-sample setting

- In the paired *t*-test the differences $Z_1 = X_1 Y_1, \dots, Z_n = X_n Y_n$ are assumed to be (approx.) from a normal distribution $N(\mu, \sigma^2)$.
- Test about the mean difference $H_0: \mu\left\{\begin{array}{c} = \\ > \\ > \end{array}\right\}0$ versus $H_1: \mu\left\{\begin{array}{c} \neq \\ > \\ < \end{array}\right\}0.$
- Test statistic $T = \frac{\bar{Z}}{s_Z/\sqrt{n}}$, with $\bar{Z} = \frac{1}{n} \sum_{i=1}^n Z_i$, $s_Z^2 = \frac{1}{n-1} \sum_{i=1}^n (Z_i \bar{Z})^2$. Under H_0 , T has the t_{n-1} -distribution.
- The analysis is simply a one sample analysis on the differences, and μ is the difference of the means of the X-population and the Y-population.

Eduard Belitser EDDA, Lecture 2 22 / 34

Paired t-test in R: graphics

The rows of the data set ashina.txt correspond to 16 subjects and give measures of pain (for chronic headache) when treated with an active drug or a placebo.

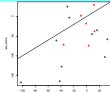

```
> ashina=read.table("ashina.txt",header=TRUE); ashina
   vas.active vas.plac grp
```

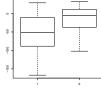

-167-102-127-39

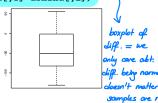

some output deleted] 16 -72 -36

> plot(vas.active~vas.plac,pch=grp,col=grp,data=ashina); abline(0,1)

not 7

The third column of the data frame ashina indicates the order of measurement (1=placebo first, 2=active first). This is used in the first plot (only) to determine the plotting character. A possible effect of the ordering of the measurements is ignored.

> t.test(ashina[,1],ashina[,2],paired=TRUE) # two sample paired t-test

Paired t-test in R: estimation and testing

```
Paired t-test
                                               عوامي على حساس على المناس ا
        ashina[, 1] and ashina[, 2]
t = -3.2269, df = 15, p-value = 0.005644 # conclusion: H0 is rejected
alternative hypothesis: true difference in means is not equal to 0
95 percent confidence interval:
 -71.1946 -14.5554
                                                                            there is a diffi
i.e. drug works
sample estimates:
mean of the differences
                   -42.875
Without paired=TRUE, t.test with 2 arguments treats 2 samples as independent.
With 1 argument t.test performs a one sample t-test. Applied to the differences this
is equivalent to a paired two sample t-test.
> t.test(ashina[,1]-ashina[,2]) # one sample t-test for differences
         One Sample t-test -> actually the same
        ashina[, 1] - ashina[, 2]
t = -3.2269, df = 15, p-value = 0.005644 # conclusion: H0 is rejected
alternative hypothesis: true mean is not equal to 0
95 percent confidence interval:
 -71.1946 -14.5554
 [ some output deleted ]
```

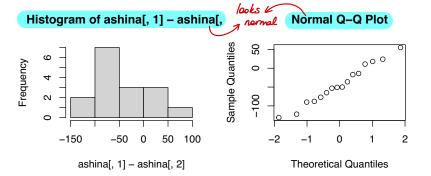

Eduard Belitser EDDA, Lecture 2 24 / 34

Paired t-test in R: diagnostics

tiff you be interest. In diff = 2 paired sample test

Conclusion from the above analysis: H_0 is rejected, i.e., the mean of the differences is different from 0. Recall that we assumed (appr.) normality of the data. Check the normality assumption on the differences (not original samples):

> par(mfrow=c(1,2));hist(ashina[,1]-ashina[,2]);qqnorm(ashina[,1]-ashina[,2])
> shapiro.test(ashina[,1]-ashina[,2]) ## gives \$p\$-value 0.9377

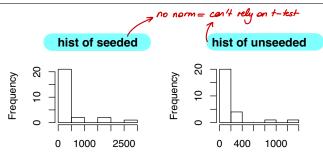

Here no reason to suspect that the differences are not taken from a normal population.

Eduard Belitser EDDA, Lecture 2 25 / 34

Example of non-normal sample

Not all data can be assumed to come from a (appr.) normal distribution. Histograms and QQ-plots can be used to check the normality assumption.

EXAMPLE Cloud seeding is a technique used to change the amount and type of precipitation, by dispersing substances into clouds. Precipitation values of seeded and unseeded clouds were measured.

Assuming normality here is clearly wrong.

Eduard Belitser EDDA, Lecture 2 26 / 34

one sample (or two paired samples) from a nonnormal distribution

One sample (or two paired samples): setting and design

Setting:

- An experiment with one numerical outcome per experimental unit. Interest is in the location (e.g., median) of the population distribution.
- An experiment with two numerical outcomes per experimental unit. Interest is in a possible difference between the locations of the two outcomes. This setting is called two paired samples (or, matched pairs).

Design:

- Take a random sample of experimental units from the relevant population.
- Measure the outcome on each unit, or measure the two outcomes on each unit (will be clearly related as the they are measured on the same unit)

EXAMPLE The number of infected people by a disease in different countries.

EXAMPLE The exam grades for a certain course. e.g. if exam is diff. or not?

EXAMPLE The blood pressure of a person before and after a drug treatment.

-> 1 unit, 2 meas. = w/ treat and w/o treat.

diff.cond.

meas

or some

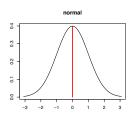

The median: recap

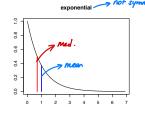

21

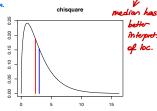

The median of a population is the middle value in the sorted populat. values. Formally: m is the median of a (contin.) random variable X if $P(X \le m) = \frac{1}{2}$.

For a given population median m, we have that $P(X < m) = P(X > m) = \frac{1}{2}$. Being bigger or smaller than the median is like tossing a fair coin.

For skewed distributions the mean is highly influenced by the high/low values. In such cases it is better to test location in terms of median instead of mean.

The more skewed, the bigger the distance between median and mean.

* for symm. dist -> no diff b.w. mean and med.

Eduard Belitser EDDA, Lecture 2 29 / 34

Setting:

Sign test for one sample or matched pairs

* only assump. here = indep. identic.ly dist. (i.i.d) for some dist . -> repet of some experiment

- A sample X_1, \ldots, X_n from some population. We want to test about the population median m.
- A sample $(Z_1, Y_1) \dots (Z_n, Y_n)$ of matched pairs from some population. We want to test about the median m of the differences $X_i = Z_i - Y_i$.

```
Hypotheses: we test H_0: m\begin{cases} \stackrel{=}{\leq} \\ \stackrel{\leq}{\leq} \end{cases} m_0 versus H_1: m\begin{cases} \stackrel{\neq}{\geq} \\ \stackrel{>}{\geq} \end{cases} m_0.
Test statistic: T = \#(i : X_i < m_0), where "#" means "the number of".
Distribution of T under H_0: exactly Bin(n, \frac{1}{2}) (a norm. approx. is possible).
```

Depending on H_1 the test is one-sided or two-sided.

```
In R: binom.test(t,n,p=0.5,alt=...) (for example, alt="g" if H_1: m > m_0)
```

-> dep. an location you are looking for (0.5 = median) If $m=m_0$, about $\frac{n}{2}$ values are expected to be bigger/smaller than m_0 . Large deviations from this indicate that H_0 may not be true. In case of matched pairs $\#(i: X_i < m_0) = \#(i: Z_i < Y_i).$

Eduard Belitser EDDA, Lecture 2 30 / 34

Sign test in R: example

```
> approx. half of shudon to should pass the course
```

We want to test whether the median exam grade is 6. Because of the small sample size, we are not sure about normality. (Grades are not always normally distributed!) Data are the exam grades of 13 randomly selected students.

Conclusion from the above output of binom.test: H_0 is not rejected.

To test the claim of interest correctly, one should reduce to the right version of the binomial test: the relevant one-sided or two sided version. For example, to test whether the exam is not too difficult, we can set $H_1: m > 6$ leading to test binom.test(9,13,p=0.5,alt="g") One can also work with other choices of statistics T, e.g., $T = \#(i: X_i > m_0)$ choose right alf.

Wilcoxon signed rank test for one sample or matched pairs

Setting:

- ** power of sign test < power of t-test (if data is nom. dist.) // sign test closes to the sign test of sign
- A sample X_1, \ldots, X_n from a symmetric population (a stronger assumption than for the sign test!). Want to test about the population median m.
- A sample $(Z_1, Y_1) \dots (Z_n, Y_n)$ of matched pairs from some population. Test about the median m of the (symm.) differences $X_i = Z_i Y_i$.

$$\text{Hypotheses: } H_0: m \left\{ \begin{array}{l} = \\ \geq \\ \geq \end{array} \right\} m_0 \text{ vs. } H_1: m \left\{ \begin{array}{l} \neq \\ > \\ < \end{array} \right\} m_0.$$

Test statistic: $T = \sum_{i:X_i > m_0} R_i$ of the ranks of $|X_i - m_0|$ over such i for which $X_i > m_0$. Large values of T indicate that $m > m_0$, small T that $m < m_0$.

Distribution of T under H_0 : known in R (normal approximation for large n).

In R: wilcox.test(data,mu=m0,alt=...) Dep. on H_1 , one- or two-sided test.

Rank of an observation is the order number assigned to it if the observations are ordered from smallest to largest. For example, the ranks of observations $X_1=3$, $X_2=5$, $X_3=2$, $X_4=7$ are $R_1=2$, $R_2=3$, $R_3=1$, $R_4=4$ resp. In R, the ranks of the sample x are computed by $\mathbf{rank}(\mathbf{x})$. Norm. approx.: $\frac{T-n(n+1)/4}{\sqrt{n(n+1)(2n+1)/24}} \sim N(0,1)$.

ost data but ranks are stable = robust stats

Wilcoxon signed rank test in R: example

The Wilcoxon signed rank test takes into account the ranks of the deviations from the proposed median m_0 . If the data is symmetric around m_0 , the ranks at both sides should be approximately equal.

Eduard Belitser EDDA, Lecture 2 33 / 34

To finish

Today we discussed:

- bootstrap confidence intervals
- bootstrap tests
- one sample (two paired samples) tests for normal and not normal samples
 - t-test
 - sign test
 - Wilcoxon signed rank test

Next time: two sample tests.
